RELEASE NOTES

1.1. 6.0 Release

New optimized routines

Following API calls were added to read bulk information about the device and speed up debugging. `ReadWarpState()` reads the whole state of a warp in a single API call. `ReadRegisterRange()` reads the value of a range of N registers in a single API call. `ResumeWarpsUntilPC()` resumes a set of warps until a given PC instead of single-stepping several times.

Adjusted Code Address

On some architectures, some PCs may be invalid and should not be referenced. To help the debugger clients, the API now provides the routine `getAdjustedCodeAddress()`. Given a code address, the function returns the corresponding valid PC.

Precise Error Reporting

Exceptions are not always precise. The device may stop at a PC other than the address of the instruction that triggered an exception. On some device architectures, it is sometimes possible to recover the address of that instruction. That address can now be retrieved using the newly introduced `readErrorPC()` API routine.

ELF Image Notification Events

When the ELF image is unloaded from the device, the debugger client is now notified with a new `CUDBG_EVENT_ELF_IMAGE_UNLOADED` event type. The ELF image load/unload events also include a new properties field that is currently only used to indicate whether an ELF image corresponds to a set of system kernels or not, which may need to be hidden from the user. Also, the ELF image events now include a handle to the actual copy of the ELF image instead of including the ELF image itself. To retrieve the ELF image, use the `getElfImageByHandle()` routine.

Unified Memory Support

Existing routines were modified to support Unified Memory and should be used instead of the old ones: `read/writeGenericMemory()` and `read/writeGlobalMemory()`. `GetManagedMemoryRegionInfo` was added to identify the address segments that are considered managed memory and that should therefore require special attention when accessed.

Cleanup on Detach

The detach procedure was simplified and is now symmetrical with the attach procedure. The debugger client must now check if the application needs to be resumed to complete the detach process, just as it is done for the attach process.

State examination on a running device

The state collection functions in the debug API will return `CUDBG_ERROR_RUNNING_DEVICE` if called without first calling `suspendDevice` to ensure the device is stopped.

Using `singleStepWarp()` in an application using CUDA Dynamic Parallelism

Due to changes in the way CUDA Dynamic Parallelism operates, the debug API's `singleStepWarp()` entry point can now return `CUDBG_ERROR_WARP_RESUME_NOT_POSSIBLE`. To correctly handle such cases, the debugger client must set a breakpoint at the return address of the current frame and must resume all devices and resume all host threads. When `singleStepWarp()` returns `CUDBG_ERROR_WARP_RESUME_NOT_POSSIBLE`, there is no guarantee that hardware state has not been modified. In particular, when running with software preemption, there is no guarantee that any GPU state is valid across the `singleStepWarp()` call. As a result, debugger clients must invalidate and reanalyze all GPU state after the call if `singleStepWarp()` returns an error.

Miscellaneous

New error values were added to support the newly added API routines. The `getNextSync/AsyncEvent()` routines were merged into a single `getNextEvent()` routine with an extra parameter instead.

Chapter 2.

INTRODUCTION

This document describes the API for the set routines and data structures available in the CUDA library to any debugger.

Starting with 3.0, the CUDA debugger API includes several major changes, of which only few are directly visible to end-users:

- ▶ Performance is greatly improved, both with respect to interactions with the debugger and the performance of applications being debugged.
- ▶ The format of cubins has changed to ELF and, as a consequence, most restrictions on debug compilations have been lifted. More information about the new object format is included below.

The debugger API has significantly changed, reflected in the CUDA-GDB sources.

2.1. Debugger API

The CUDA Debugger API was developed with the goal of adhering to the following principles:

- ▶ Policy free
- ▶ Explicit
- ▶ Axiomatic
- ▶ Extensible
- ▶ Machine oriented

Being explicit is another way of saying that we minimize the assumptions we make. As much as possible the API reflects machine state, not internal state.

There are two major "modes" of the devices: stopped or running. We switch between these modes explicitly with `suspendDevice` and `resumeDevice`, though the machine may suspend on its own accord, for example when hitting a breakpoint.

Only when stopped, can we query the machine's state. Warp state includes which function is it running, which block, which lanes are valid, etc.

As of CUDA 6.0, state collection functions in the debug API will return `CUDBG_ERROR_RUNNING_DEVICE` if called without first calling the `suspendDevice` entry point to ensure the device is stopped.

2.2. ELF and DWARF

CUDA applications are compiled in ELF binary format.

Starting with CUDA 6.0, DWARF device information is obtained through an API call of `CUDBGAPI_st::getElfImageByHandle` using the handle exposed from `CUDBGEvent` of type `CUDBG_EVENT_ELF_IMAGE_LOADED`. This means that the information is not available until runtime, after the CUDA driver has loaded. The DWARF device information lifetime is valid until it is unloaded, which presents a `CUDBGEvent` of type `CUDBG_EVENT_ELF_IMAGE_UNLOADED`.

In CUDA 5.5 and earlier, the DWARF device information was returned as part of the `CUDBGEvent` of type `CUDBG_EVENT_ELF_IMAGE_LOADED`. The pointers presented in `CUDBGEvent55` were read-only pointers to memory managed by the debug API. The memory pointed to was implicitly scoped to the lifetime of the loading CUDA context. Accessing the returned pointers after the context was destroyed resulted in undefined behavior.

DWARF device information contains physical addresses for all device memory regions except for code memory. The address class field (`DW_AT_address_class`) is set for all device variables, and is used to indicate the memory segment type (`ptxStorageKind`). The physical addresses must be accessed using several segment-specific API calls.

For memory reads, see:

- ▶ `CUDBGAPI_st::readCodeMemory()`
- ▶ `CUDBGAPI_st::readConstMemory()`
- ▶ `CUDBGAPI_st::readGlobalMemory()`
- ▶ `CUDBGAPI_st::readParamMemory()`
- ▶ `CUDBGAPI_st::readSharedMemory()`
- ▶ `CUDBGAPI_st::readLocalMemory()`
- ▶ `CUDBGAPI_st::readTextureMemory()`

For memory writes, see:

- ▶ `CUDBGAPI_st::writeGlobalMemory()`
- ▶ `CUDBGAPI_st::writeParamMemory()`
- ▶ `CUDBGAPI_st::writeSharedMemory()`
- ▶ `CUDBGAPI_st::writeLocalMemory()`

Access to code memory requires a virtual address. This virtual address is embedded for all device code sections in the device ELF image. See the API call:

- ▶ `CUDBGAPI_st::readVirtualPC()`

Here is a typical DWARF entry for a device variable located in memory:

```
<2><321>: Abbrev Number: 18 (DW_TAG_formal_parameter)
  DW_AT_decl_file   : 27
  DW_AT_decl_line   : 5
  DW_AT_name        : res
  DW_AT_type        : <2c6>
  DW_AT_location    : 9 byte block: 3 18 0 0 0 0 0 0 0 (DW_OP_addr: 18)
  DW_AT_address_class: 7
```

The above shows that variable 'res' has an address class of 7 (ptxParamStorage). Its location information shows it is located at address 18 within the parameter memory segment.

Local variables are no longer spilled to local memory by default. The DWARF now contains variable-to-register mapping and liveness information for all variables. It can be the case that variables are spilled to local memory, and this is all contained in the DWARF information which is ULEB128 encoded (as a DW_OP_regx stack operation in the DW_AT_location attribute).

Here is a typical DWARF entry for a variable located in a local register:

```
<3><359>: Abbrev Number: 20 (DW_TAG_variable)
  DW_AT_decl_file   : 27
  DW_AT_decl_line   : 7
  DW_AT_name        : c
  DW_AT_type        : <1aa>
  DW_AT_location    : 7 byte block: 90 b9 e2 90 b3 d6 4 (DW_OP_regx:
160631632185)
  DW_AT_address_class: 2
```

This shows variable 'c' has address class 2 (ptxRegStorage) and its location can be found by decoding the ULEB128 value, DW_OP_regx: 160631632185. See `cuda-tdep.c` in the `cuda-gdb` source drop for information on decoding this value and how to obtain which physical register holds this variable during a specific device PC range.

Access to physical registers liveness information requires a 0-based physical PC. See the API call:

- ▶ `CUDBGAPI_st::readPC()`

2.3. ABI Support

ABI support is handled through the following thread API calls:

- ▶ `CUDBGAPI_st::readCallDepth()`
- ▶ `CUDBGAPI_st::readReturnAddress()`
- ▶ `CUDBGAPI_st::readVirtualReturnAddress()`

The return address is not accessible on the local stack and the API call must be used to access its value.

For more information, please refer to the ABI documentation titled "Fermi ABI: Application Binary Interface".

2.4. Exception Reporting

Some kernel exceptions are reported as device events and accessible via the API call:

- ▶ `CUDBGAPI_st::readLaneException()`

The reported exceptions are listed in the `CUDBGException_t` enum type. Each prefix, (Device, Warp, Lane), refers to the precision of the exception. That is, the lowest known execution unit that is responsible for the origin of the exception. All lane errors are precise; the exact instruction and lane that caused the error are known. Warp errors are typically within a few instructions of where the actual error occurred, but the exact lane within the warp is not known. On device errors, we *may* know the *kernel* that caused it. Explanations about each exception type can be found in the documentation of the struct.

Exception reporting is only supported on Fermi (sm_20 or greater).

2.5. Attaching and Detaching

The debug client must take the following steps to attach to a running CUDA application:

1. Attach to the CPU process corresponding to the CUDA application. The CPU part of the application will be frozen at this point.
2. Check to see if the `CUDBG_IPC_FLAG_NAME` variable is accessible from the memory space of the application. If not, it implies that the application has not loaded the CUDA driver, and the attaching to the application is complete.
3. Make a dynamic function call to the function `cudbgApiInit()` with an argument of "2", i.e., "`cudbgApiInit(2)`". This causes a helper process to be forked off from the application, which assists in attaching to the CUDA process.
4. Ensure that the initialization of the CUDA debug API is complete, or wait till API initialization is successful.
5. Make the "`initializeAttachStub()`" API call to initialize the helper process that was forked off from the application earlier.
6. Read the value of the `CUDBG_RESUME_FOR_ATTACH_DETACH` variable from the memory space of the application:
 - ▶ If the value is non-zero, resume the CUDA application so that more data can be collected about the application and sent to the debugger. When the application is resumed, the debug client can expect to receive various CUDA events from

the CUDA application. Once all state has been collected, the debug client will receive the event `CUDBG_EVENT_ATTACH_COMPLETE`.

- ▶ If the value is zero, there is no more attach data to collect. Set the `CUDBG_IPC_FLAG_NAME` variable to 1 in the application's process space, which enables further events from the CUDA application.
7. At this point, attaching to the CUDA application is complete and all GPUs belonging to the CUDA application will be suspended.

The debug client must take the following steps to detach from a running CUDA application:

1. Check to see if the `CUDBG_IPC_FLAG_NAME` variable is accessible from the memory space of the application, and that the CUDA debug API is initialized. If either of these conditions is not met, treat the application as CPU-only and detach from the application.
2. Next, make the "clearAttachState" API call to prepare the CUDA debug API for detach.
3. Make a dynamic function call to the function `cudbgApiDetach()` in the memory space of the application. This causes CUDA driver to setup state for detach.
4. Read the value of the `CUDBG_RESUME_FOR_ATTACH_DETACH` variable from the memory space of the application. If the value is non-zero, make the "requestCleanupOnDetach" API call.
5. Set the `CUDBG_DEBUGGER_INITIALIZED` variable to 0 in the memory space of the application. This makes sure the debugger is reinitialized from scratch if the debug client re-attaches to the application in the future.
6. If the value of the `CUDBG_RESUME_FOR_ATTACH_DETACH` variable was found to be non-zero in step 4, delete all breakpoints and resume the CUDA application. This allows the CUDA driver to perform cleanups before the debug client detaches from it. Once the cleanup is complete, the debug client will receive the event `CUDBG_EVENT_DETACH_COMPLETE`.
7. Set the `CUDBG_IPC_FLAG_NAME` variable to zero in the memory space of the application. This prevents any more callbacks from the CUDA application to the debugger.
8. The client must then finalize the CUDA debug API.
9. Finally, detach from the CPU part of the CUDA application. At this point all GPUs belonging to the CUDA application will be resumed.

CUDBGResult (*CUDBGAPI_st::resumeWarpsUntilPC) (uint32_t devId, uint32_t sm, uint64_t warpMask, uint64_t virtPC)

Inserts a temporary breakpoint at the specified virtual PC, and resumes all warps in the specified bitmask on a given SM. As compared to `CUDBGAPI_st::resumeDevice`, `CUDBGAPI_st::resumeWarpsUntilPC` provides finer-grain control by resuming a selected set of warps on the same SM. The main intended usage is to accelerate the single-stepping process when the target PC is known in advance. Instead of single-stepping each warp individually until the target PC is hit, the client can issue this API. When this API is used, errors within CUDA kernels will no longer be reported precisely. In the situation where resuming warps is not possible, this API will return `CUDBG_ERROR_WARP_RESUME_NOT_POSSIBLE`. The client should then fall back to using `CUDBGAPI_st::singleStepWarp` or `CUDBGAPI_st::resumeDevice`.

Parameters**devId**

sm

- the SM index

warpMask

- the bitmask of warps to resume (1 = resume, 0 = do not resume)

3.10. Events

One of those events will create a [CUDBGEvent](#):

- ▶ the elf image of the current kernel has been loaded and the addresses within its DWARF sections have been relocated (and can now be used to set breakpoints),
- ▶ a device breakpoint has been hit,
- ▶ a CUDA kernel is ready to be launched,
- ▶ a CUDA kernel has terminated.

When a [CUDBGEvent](#) is created, the debugger is notified by calling the callback functions registered with `setNotifyNewEventCallback()` after the API struct initialization. It is up to the debugger to decide what method is best to be notified. The debugger API routines cannot be called from within the callback function or the routine will return an error.

Upon notification the debugger is responsible for handling the [CUDBGEvents](#) in the event queue by using [CUDBGAPI_st::getNextEvent\(\)](#), and for acknowledging the debugger API that the event has been handled by calling [CUDBGAPI_st::acknowledgeEvent\(\)](#). In the case of an event raised by the device itself, such as a breakpoint being hit, the event queue will be empty. It is the responsibility of the debugger to inspect the hardware any time a [CUDBGEvent](#) is received.

Example:

```

[CUDBGEvent event;
  CUDBGResult res;
  for (res = cudbgAPI->getNextEvent(&event);
       res == CUDBG_SUCCESS && event.kind != CUDBG_EVENT_INVALID;
       res = cudbgAPI->getNextEvent(&event)) {
    switch (event.kind)
    {
      case CUDBG_EVENT_ELF_IMAGE_LOADED:
        //...
        break;
      case CUDBG_EVENT_KERNEL_READY:
        //...
        break;
      case CUDBG_EVENT_KERNEL_FINISHED:
        //...
        break;
      default:
        error(...);
    }
  }
}

```

See `cuda-tdep.c` and `cuda-linux-nat.c` files in the `cuda-gdb` source code for a more detailed example on how to use `CUDBGEvent`.

CUDBGResult (*resumeWarpsUntilPC) (uint32_t devId, uint32_t sm, uint64_t warpMask, uint64_t virtPC)

Inserts a temporary breakpoint at the specified virtual PC, and resumes all warps in the specified bitmask on a given SM. As compared to CUDBGAPI_st::resumeDevice, CUDBGAPI_st::resumeWarpsUntilPC provides finer-grain control by resuming a selected set of warps on the same SM. The main intended usage is to accelerate the single-stepping process when the target PC is known in advance. Instead of single-stepping each warp individually until the target PC is hit, the client can issue this API. When this API is used, errors within CUDA kernels will no longer be reported precisely. In the situation where resuming warps is not possible, this API will return CUDBG_ERROR_WARP_RESUME_NOT_POSSIBLE. The client should then fall back to using CUDBGAPI_st::singleStepWarp or CUDBGAPI_st::resumeDevice.

Parameters**devId**
